ABSTRACT

Previous literature has explored sex differences to explain differences in cognition and behavior. If there are sex differences in the brain, how would these differences alter our perception of treatment and diagnosis in a clinical population, such as people with schizophrenia? In our study, we wanted to find out whether there is an effect of sex on cortical thickness (CT) in the parietal lobule and cognitive measures of verbal memory, verbal learning, attention, spatial reasoning, and working memory in healthy controls (HC) and people with schizophrenia (SZ). We additionally explored relationships between cognition and parietal lobule CT. RESULTS: There is no effect of sex on cognition and CT in the parietal lobule, but we found differences in correlations between CT and cognition in each sex and diagnosis group. DISCUSSION: Further research is necessary to discover whether clinicians need to consider gender in the treatment of people with schizophrenia.

DEDICATION

I would like to dedicate this project to my one and only “favorite” sister, Natasha, AKA Sha-sha. She is the reason why I asked these questions and is my biggest motivator for following my dreams in the field of psychology. If it were not for our experiences together, the good and the bad, I would have never become the person I am today. Thank you for being such an amazing inspiration.
ACKNOWLEDGEMENTS

I appreciate Dr. Turner for taking the time to guide me on my research, as well as helping me understand my topic further so that I can become a better researcher. I would also like to express my gratitude to my fellow lab mates at the Imaging & Neuroinformatics lab for shedding light on various topics of interest and inspiring me to work diligently. I could not have asked for a better team of scholars.

INTRODUCTION

Ever since John Gray (1992) proposed that men are from Mars and women are from Venus, researchers have conducted studies to find out if this notion was certainly the case. Over the last 50 years, researchers wanted to explore sex differences in the brain to explain our differences in cognition and behavior. There have been numerous studies conducted on differences in brain size and tissue, as well as studies that looked into differences in cognition. It is important to investigate these differences in clinical populations, such as people with schizophrenia, to see whether each sex must be provided with different types of treatment due to the possible differences in the expression of the illness and the severity of the illness between male and female patients.

General Sex Differences in Cognition and Brain Structure

Studies on sex differences as early as the 19th century discovered that male brains were bigger than female brains. Findings on brain size have remained consistent, further supported by magnetic resonance imaging (MRI) studies on brain tissue. MRI studies have revealed not only sex differences in brain size, but also in cortical thickness, which refers to the combined thickness of the outer layers composed of gray matter in the cerebral cortex. Compared to men, women have greater cortical thickness (Im et al, 2006; Mutlu et al., 2013; Plessen, Hugdahl, Bansal, Hao, & Peterson, 2014; Sowell et al., 2007). Recent studies have found that cortical thickness is an important measurement of brain structure because the thickness of the cortex might indicate a level of intelligence, due to its relationship with gray matter volume (Choi et al., 2008; Karama et al, 2009; Narr et al, 2007). If cortical thickness positively correlates with intelligence, what does this tell us about the difference in cortical thickness between men and women? Does cortical thickness additionally predict cognitive ability?
Many studies have explored sex differences in cognitive abilities. Researchers have utilized a wide range of cognitive measures, such as those that assess memory, attention, and verbal learning. Women generally score higher on cognitive measures than men, and they often excel at measures of verbal reasoning. On the other hand, men almost always have the upper hand on spatial reasoning tasks. Researchers have asked and wondered what was the explanation for these cognitive differences. One common theory is that sex differences in brain structure, particularly the parietal lobule, may explain the differences found in cognition.

**Sex Differences in the Parietal Lobule**

The parietal lobe is a key area for research on sex differences in the brain. As mentioned previously, many studies have found that women’s cortical thickness is greater than men’s in this region. Functional MRI studies have indicated that the parietal lobule activates when performing spatial reasoning tasks (Culham & Kanwisher, 2000; Save & Poucet, 2000; Seurinck, Vingerhoets, de Lange, 2004). For example, Koscik et al. (2009) studied whether there was a relationship between the scores on the Mental Rotations Test (MRT) and the parietal lobe, and whether there were sex differences in that region. Their results revealed that not only did men score better on MRT than women, but men also had greater surface area in the parietal lobe than women; they concluded that this finding may account for the disadvantage that women have in spatial reasoning tasks. This sexual dimorphism confirms the need for further research on sex differences in that region.

**Sex Differences in Cognition and Brain Structure in Schizophrenia**

Do these sex differences apply to a clinical population, such as people with schizophrenia? Schizophrenia is characterized as portraying symptoms that causes patients to have a distorted sense of reality. They exhibit positive symptoms of hallucinations, delusion, and
grandeur while additionally displaying negative symptoms of blank affect and social withdrawal. Regarding its effect on the brain, due to the severity of the illness, people with schizophrenia have less gray matter, thinner cortices, and less brain volume than the healthy population (Hulshoff et al., 2002; Kuperberg et al., 2003; Schultz et al., 2010; van Haren et al., 2011). Regarding cognition, people with schizophrenia tend to perform poorly compared with their healthy counterparts, especially in areas of attention, working memory, and executive functioning (Bilders et al., 2002; Caspi et al., 2003; Cornblatt et al., 1985; Gold et al., 1997; McGurk et al., 2004; Pantelis et al., 1999).

Sex differences in people with schizophrenia tend to be similar to that of the healthy population. Women with schizophrenia tend to perform better on cognitive tests than men with schizophrenia (Han et al., 2012; Ittig et al., 2015; Longenecker, Dickinson, Weinberger, & Elvevag, 2010; Roesch-Ely et al., 2009; Torniainen et al., 2011; Vaskinn et al., 2011). This could be due to sexual dimorphisms found in schizophrenia literature regarding the age of onset, which occurs earlier in men, and the effects of estrogen as a protective factor for women (Aloysi, Van Dyk, & Sano, 2006; Heringa, Begemann, Goverde, & Sommer, 2015; Kulkarni et al., 2008; Salokangas, 1993; van der Leeuw et al., 2013). In terms of structure, Frederikse et al. (2000) found that when investigating sex differences between a healthy population and people with schizophrenia, there is a clear distinction found in gray matter volume in the parietal lobe between healthy men and men with schizophrenia; as for the women, there were surprisingly no significant differences between healthy women and women with schizophrenia.

**Purpose of Our Study**

If these sex differences truly exist in people with schizophrenia, it seems like clinicians should take these findings into account when developing a treatment plan for each sex, rather
than generalizing the treatment plan for all people with schizophrenia. In our study, we examined cortical thickness in relation to cognition in people with schizophrenia to see whether our results remain consistent with the results of previous literature, as well as build off of Frederikse et al.’s (2000) findings by focusing on differences found particularly in the parietal lobe. We additionally wanted to see whether there was an effect of sex on cortical thickness and cognition, or if the interaction between sex and diagnosis would have an effect on both measures.

**METHOD**

*Participants.* The sample consisted of 175 participants, with 87 identifying as healthy controls (HC) and 88 people with schizophrenia or schizoaffective disorder (SZ). There were a total of 136 men and 39 women in the dataset. Table 1 summarizes the age, gender, handedness, education status, and duration of illness of our participants.

*MRI Acquisition.* We obtained the Centers of Biomedical Research Excellence (COBRE) dataset from the Mind Research Network (MRN) in Albuquerque, New Mexico. At MRN, a Siemens TIM Trio 3T scanner was used to collect MRI data using a 12-channel head coil.
**Cognitive Battery.** The COBRE dataset included an extensive cognitive battery. For our study, we obtained the scores of our participants from the Hopkins Verbal Learning Test Immediate (HVLT-I) & Delay (HVLT-D) to assess both verbal learning and verbal memory; the Continuous Performance Test—Identical Pairs Version (CPT-IP) to assess attention; the Neuropsychological Assessment Battery (NAB) Mazes Test to assess spatial reasoning; and the Wechsler Memory Scale—Third Edition (WMS-III) to assess working memory.

**Cortical Thickness Measures.** We utilized Freesurfer, a brain imaging software, to extract cortical thickness measures of the various regions of the parietal lobule: inferior parietal lobule (IPL), superior parietal lobule (SPL), supramarginal gyrus (SMG), precuneus (PCUN), and postcentral gyrus (PoCG).

**Statistical Analyses.** We utilized SPSS 21 to conduct analyses among cortical thickness measures and cognitive battery scores. We analyzed the program’s marked outliers of cortical thickness by looking at the MRI scans of the participants to see whether the cortical thickness was true to size. A multivariate analysis of covariance (MANCOVA) was conducted to test whether there was an effect of gender or a three-way interaction between gender and diagnosis on cortical thickness in the parietal lobule region while using age as a covariate. A multivariate analysis of variance (MANOVA) to see if there is an effect of gender on cognition. We also conducted partial correlations between each cognitive measure and cortical thickness in all regions of the parietal lobule while co-varying for age across diagnosis and gender.

**RESULTS**

**The Effect of Gender & Diagnosis on Cognition**

Results of the MANOVA are summarized in Table 2. The MANOVA revealed that there was no significant effect of gender, neither an effect of a two-way interaction of gender x
diagnosis on cognition. However, diagnosis type had a statistically significant effect on all
cognitive measures. Figures 1-5 provide a graph of each result.

The Effect of Gender & Diagnosis on Cortical Thickness

Results of the MANCOVA are summarized in Table 3. The MANCOVA revealed that there was no significant effect of gender, neither an effect of gender x diagnosis on cognition.

Like the results in cognition, diagnosis type had a statistically significant effect on the following regions’ cortical thickness: left IPL ($F (1, 170) = 7.47$, $p = .007$; right IPL, ($F (1, 170) = 9.79$, $p = .002$; left SPL, ($F (1, 170) = 4.07$, $p = .045$; left SMG, ($F (1, 170) = 14.35$, $p = .000$; and right SMG, ($F (1, 170) = 9.94$, $p = .002$. Figures 6-10 provided a graph for each significant result.

**Partial Correlation between Cognition and Cortical Thickness**

A Pearson product-moment correlation coefficient was computed to assess the relationship between parietal lobule CT and cognitive measures. The results are summarized in Table 4. Across gender, a scatterplot depicts two positive correlations shared by men and women: the right PCUN and CPT-IP, and the left SMG and CPT-IP. In women, various correlations were found between cortical thickness and verbal memory, and only one correlation found between the right IPL and verbal learning. However, after testing for a Bonferroni correction \((p < .001),\) none of the correlations in men were significant, but in women, there was a
close to significant, positive correlation between the right IPL and HVLT-D, $r = 0.41$, $n = 39$, $p = 0.002$. Greater cortical thickness in the right IPL was associated with a higher HVLT-D score in women. Figure 11 depicts correlations between female controls and female patients in the relationship between the right IPL and HVLT-D score.

Across diagnosis, no significant correlations were found in controls; however, two significant, positive correlations were found in patients between the right precuneus and CPT-IP, $r = .26$, $n = 85$, $p = .019$ and between the left supramarginal gyrus and CPT-IP, $r = .22$, $n = 85$, $p = .046$. Neither correlation passed the Bonferroni correction. Summary of the correlations can be referred to in Table 5.

Note: *p < .05; **p < .01
Figure 11. Partial Correlation between the Right IPL and Verbal Memory in Female Participants. After applying the Bonferroni correction, there was a close to significant, positive correlation between the right inferior parietal lobule and verbal memory, $r = 0.41$, $n = 39$, $p = .002$. Across diagnosis type, there were no significant correlations in female controls, $r = 0.39$, $n = 23$, $p = .070$, or female patients, $r = .04$, $n = 16$, $p = 0.873$.

**DISCUSSION**

No significant gender differences were found in cortical thickness and cognition in our study. There have been studies that have had similar findings with ours, indicating that this may be due to individual differences in the particular sample of study (Albus et al., 1997; Bozikas et
al., 2010; Gogos et al., 2010). The effect of diagnosis on cognition and structure is consistent with previous literature regarding the differences in cognition and structure between healthy population and schizophrenic population, with patients showing worse cognitive performance and thinner cortices than healthy controls. In terms of correlations, there was a close to significant correlation between the right inferior parietal lobule and verbal memory in female participants, which makes us question what is significant about the inferior parietal lobule and how it could be involved in verbal memory.

**The Inferior Parietal Lobule**

The inferior parietal lobule, composed of the angular gyrus and supramarginal gyrus, was originally thought to be involved in motor planning (Cohen et al., 1994; Snyder et al., 1998). Recently, because Freesurfer software separately distinguishes between the inferior parietal lobule and the supramarginal gyrus, we were mostly working with the angular gyrus within the inferior parietal lobule (Desikan et al., 2005). The angular gyrus is part of the Default Mode Network, which is activated when an individual’s mind is simply wandering and not focused on a task (Buckner, Andrews-Hanna, & Schacter, 2008). The angular gyrus has additionally been noted in studies of verbal working memory, episodic and semantic memory, creativity, and self-awareness (Bellana, Liu, Anderson, Moscovitch, & Grady, 2015; Ciaramelli et al, 2008; Jung et al, 2010; Park, Kirk, & Waldie, 2015; Sui, Chechlacz, & Humphreys, 2012). The inferior parietal lobule is additionally one of the many prominent regions in verbal memory circuitry in women (Abbs, Liang, Makri, Tsuang, & Seidman, 2011).

**Limitations**

Our sample size consisted of 136 male participants and 39 female participants, which suggests that for every woman in our study, there were three men added to the sample. Including
extra female participants in our study could have the potential to alter some of their results we have received in this study. Additionally, the majority of the patients in our sample were, if not all, medicated before completing the cognitive tests, which may have allowed them to perform accordingly than if they were not medicated. Unlike Frederikse et al., we solely focused on cortical thickness rather than measuring differences in gray matter volume, surface area, and asymmetry. Although cortical thickness and gray matter volume are related, they are certainly not the same thing, which may account for why our findings were not similar to that of Frederikse et al. Perhaps we could include these measures in the future to see whether there are sex differences across those particular domains. We focused specially on the parietal lobule region, which may contribute to only some cognitive processes in the measures that we chose for our study. Considering other regions, such as the frontal or temporal regions, may contribute to differences in correlations between structure and cognition. Additional cognitive measures are also worth questioning to see whether there are other forms of cognition in which we can mark gender differences.

Conclusions

In conclusion, our results indicate that there is no influence of gender on cognition and structure in the participants of our sample. The only concern seems to be revolved around the clinical condition of the patient, and recognition of how their illness is contributing to cognitive impairment or cortical thinning is certainly essential to bear in mind. We do need to contemplate on the role of the inferior parietal lobe in women, as well as in people with schizophrenia. Further research is necessary to determine whether we genuinely need to consider gender differences in areas of cognition and brain structure in schizophrenia, and whether this knowledge is imperative for clinicians who treat patients of this clinical population.
